Abstract

The researchers use Bayesian meta-analysis methods to estimate the impact of unconditional cash transfers (UCTs) on twelve primary outcomes from 114 studies of 72 UCT programs in middle- and low-income countries. Cash transfers generate strong and positive average treatment effects on ten of thirteen outcomes: monthly household total and food consumption, monthly income, labor supply, school enrollment, food security, psychological well-being, total assets, financial assets, and children height-for-age. The three remaining outcomes have prediction intervals mostly positive, but that include zero: number of hours worked, children weight-forage, and stunting. The researchers draw six conclusions: First, consistent with several models of capital market failures, households consume more of streams and invest more of lump sums, however once stream programs end the impacts mirror those of lump sum, indicating some propensity to save a portion of stream transfers. Second, long-run treatment effects remain broadly strong, with some evidence of lump sums modestly dissipating impact while ongoing streams augmenting impact. Third, returns are linear or slightly negative with respect to grant amount, thus we do not find evidence for threshold-based poverty traps within the observed range of transfers and with this study-level analytical method. Fourth, effects on consumption and income are greater for UCTs targeted to women. Fifth, programs employing light-touch framing related to child welfare or food security have weakly stronger impacts. Sixth, positive impacts on labor supply and income suggest no evidence of "dependency" theories that cash transfers demotivate income-generating activity on average.

1 Introduction

Unconditional cash transfers (UCTs) have become a common policy tool and are heavily studied. At least 72 UCT programs have been evaluated using a randomized controlled trial ("RCT"), ranging widely in scale and purpose, from large government programs to small non-governmental efforts, from humanitarian aid to economic development. The breadth of this empirical evidence now permits us to establish a basic understanding of the average expected treatment effects from cash transfers across a variety of important outcomes, potentially serving as a benchmark for development policy. The plethora of studies and design variations facilitate investigations of several commonly posed theoretical and policy questions of critical importance, such as the presence of threshold-based poverty traps, the elasticity of labor supply to income, the differential impact from targeting women within households and from adding framing (i.e. "nudges") to the transfers.

Our meta-analysis includes 114 papers ("studies") reporting results from 72 randomized evaluations ("programs") of UCTs in 34 low and middle income countries over both short and long time horizons (mostly between 12 and 48 months).¹ We examine impacts on 13 primary as well as several secondary outcomes (typically components of a primary outcome). We also explore heterogeneity with respect to the following sources of variation: transfer size (with both a linear specification, the primary specification throughout, and a quadratic specification, to test for increasing or decreasing marginal returns to grant size), frequency of transfer (lump-sum transfers versus ongoing streams versus completed streams), measurement timing (i.e., amplification or dissipation of effects over time), target population (female-targeted versus male-targeted versus non-targeted), and framings that suggest a child or food security focus to households.

We use a Bayesian hierarchical model to jointly estimate average treatment effects of UCT programs. We find strong, positive impacts on ten of thirteen primary outcomes: Monthly household consumption, monthly household food consumption, monthly income, labor force participation (binary), school enrollment (binary), z-scores for food security

¹Appendix Tables A.1a-b describe the key design features of the 72 programs in our sample.

and for psychological well-being, the stock of total assets, the stock of financial assets, and height-for-age z-scores. Results for hours worked, weight-for-age z-scores, and stunting (binary) are positive but not statistically significant at 95% credibility.

We examine six main hypotheses. First, we find support for an oft-hypothesized pattern that people consume more of streams and invest more of lump-sums. Perhaps surprising, however, completed stream programs generate results much closer to lump sum transfers than to ongoing streams, suggesting that households are able, and choose to, save or borrow sufficiently to roughly equilibrate the two types of transfer (once the stream transfers are no longer incoming).

Second, we compare longer-run to shorter-run results. Lump sum and completed streams produce impacts that after two years modestly dissipate for consumption but remain constant for assets; ongoing stream, on the other hand, generates increasing treatment effects over time for consumption, consistent with households consuming some and investing some of the monthly stream transfers. Few papers however report long-run outcomes past 48 months.

Third, we examine whether impacts are linear (versus concave or convex) with respect to transfer size. Asset threshold-based poverty traps are a central idea of development economics and an important motivation for the use of unconditional (and large enough) cash transfers to deliver development aid. Fixed costs or increasing returns may imply an asset threshold below which investments are not worthwhile and, in the presence of binding barriers to saving and borrowing, poverty may beget poverty. In theory, a large enough temporary cash transfer could break such a cycle, but our estimates are fairly close to linear with respect to grant size. Absence of evidence, however, is not evidence of absence. This test does not rule out asset-based poverty traps as thresholds as they may be heterogeneous across sites, households, or beyond the range of transfer sizes tested; in short, this is a weak test of such theories, particularly given the analysis is at the study-level across sites and countries, and not at the household level.

Fourth, we examine how results differ for programs that target women: targeted

transfers lead to higher observed consumption and higher income (versus untargeted programs), but no difference in assets. On child-related outcomes, we find inconsistent results, with results stronger for weight-for-age of children but worse on height-for-age.

Fifth, we find that programs that include some form of a "nudge" (Thaler and Sunstein 2009) with respect to the transfer being intended to benefit children do lead to stronger impacts on total consumption, food consumption, food security, and psychological well-being but no difference for the more obvious outcomes of child anthropometrics and school enrollment.

Sixth, on labor supply, a key outcome of policy interest, unconditional cash transfers generate a strong positive effect on the extensive margin and a noisier but positive point estimate on the intensive margin (i.e., hours worked). Considering the strong positive effects on income, this implies that unconditional cash transfers do not "demotivate" recipients. This result is consistent with previous meta-analysis (Banerjee, Hanna, et al. 2017) and with poverty-trap models of labor supply in which poor households supply less labor because they need resources to find and maintain labor or to make investments for self-employment. The positive impact on labor supply is also consistent with imperfect labor markets and an increased demand for labor in the household due to downstream investments facilitated by the transfers received.²

Table 1 situates our study in the context of the extant meta-analytical literature on the impacts of cash transfer programs on particular outcome classes. We add to this meta-analysis literature along five dimensions.

First, we explicitly account for transfer size in estimating treatment effects instead of coding transfer receipt as a binary. This is consistent with Kondylis and Loeser (2021), the closest meta-analysis to ours in method and questions. Aggregating treatment effects from "any cash transfer" as a binary rather than per dollar of the transfer renders the aggregate point estimate uninterpretable on its own. One would always need to multiply

²Increased spending on temptation goods is another oft-hypothesized deleterious effect of cash transfers. We do not analyze these anew, as a recent meta-analysis reports of 42 studies finds mostly nulls or even negative point estimates, indicating that similar to labor supply the fears of increased spending on temptation goods are unsupported by the evidence (Evans and Popova 2017).

the binary point estimate for "any cash transfer" by average grant amount across studies to be interpretable (after also assuming that marginal treatment effects are constant with respect to grant size).

Second, we analyze a wide range of social and economic outcomes, while most existing meta-analyses focus on a particular outcome class (e.g., education, mental health, child health etc). These other studies are accompanied by more nuanced and theoretically deep discussions of the link between cash transfers and a particular set of outcomes, while ours is a more comparative perspective. On this dimension, the closest study to ours is Kabeer and Waddington (2015) which spans consumption, investment, and labor.

Third, we investigate the temporal evolution of impacts using a binary model that compares short-term and long-term impacts as well as a polynomial model that adds a covariate for months since the intervention and its squared term. This analysis complements three other analyses, Wollburg et al. (2023), McGuire et al. (2022), and Kondylis and Loeser (2021), that quantify effect dissipation in different ways. Closest to this paper's binary dynamic effects model, Wollburg et al. (2023) compares short-run to more long-run estimates of mostly UCT RCTs on mental health outcomes to show that small but statistically significant short-run effects on depression dissipate substantially in the longer run. McGuire et al. (2022), using a more diverse sample including both RCTs and non-randomized designs as well as CCTs and UCTs, finds little dissipation of the small effects they estimate on depression. Employing a model that uses a continuous time variable similar to our dynamic effects polynomial model, Kondylis and Loeser (2021) studies treatment effect persistence specifically with respect to transfer size and finds that the impact of larger transfers dissipates at higher rates. Our study does not detect evidence of dissipation of effects on household consumption and instead finds some evidence that effects compound over time for ongoing transfer streams.

Fourth and fifth, we examine heterogeneity in impacts with respect to targeting females (versus males, and versus untargeted) and with respect to child-focused framed (or "nudge") cash transfers, i.e., that are accompanied with either labels or some communication aspect promoting the cash transfers as intended for children's wellbeing.

2 Data

2.1 Study inclusion

Our meta-analysis focuses on RCTs of UCT programs in low and middle income countries. Following the approach by Croke et al. (2016) and Kondylis and Loeser (2021), we identify studies using two approaches. First, we gather studies from secondary sources: the GiveDirectly Cash Evidence Explorer, the Overseas Development Institute's 2016 report "Cash transfers: what does the evidence say?" (*Cash Evidence Explorer* 2023; Bastagli et al. 2016), and existing meta-analyses on cash transfers with publicly available data. Second, we conduct a search of databases and registers of scholarly research using key words.³ As displayed in Figure 1, our combined search yields a universe of 6,949 studies, of which 114 meet the inclusion criteria of our meta-analysis.

We employ the following inclusion criteria:

- 1. The study is an RCT in which the control group received no or minimal cash.
- 2. At least one of the study's treatment arms is an UCT.
 - (a) This may include UCT programs with some minimal behavioral change components to the treatment, such as an onsite information session or labelled cash transfers. It excludes conditional cash transfers (CCTs), which require ongoing behavioral compliance with certain conditions to continue receiving the cash transfer (most commonly school attendance).⁴
 - (b) This includes non-contributory pension programs.

 $^{^{3}}$ See Figure 1 for a complete description of our systematic search and Appendix Table A.2 for a hyper-linked list of the 114 included papers from the 72 studies.

⁴Two programs in our sample, Bono de Desarrollo Humano (BDH) in Ecuador and Programa de Apoyo Alimentario (PAL) in Mexico, were nominally conditional cash transfers. In practice, PAL's conditions were not enforced, and participants mostly did not adhere to them (Avitabile et al. 2019). The BDH's conditions were never implemented due to administrative constraints (Hidrobo and Fernald 2013).

- (c) This excludes RCTs with cash transfers that are delivered in conjunction with other costly and non-trivial interventions, such as training, savings group formation, coaching, etc.
- 3. The study's experiment takes place in a low or middle income country (as defined by World Bank classification).
- 4. The study reports results on any outcomes related to consumption, food security, income, savings and investment, business performance, labor supply, child health and development, education, psychological well-being.

2.2 Data extraction

We collect the following information each included study:

Transfer frequency: Lump sum and stream transfers: As an important example of program design, we distinguish between stream and lump sum transfer programs. In general terms, a lump sum transfer delivers a one-off payment, while a stream transfer delivers repeated cash payments at regular intervals over an extended period of time. We define an intervention as a lump sum program if the cash is delivered in no more than three installments over no more than two months (28 out of 34 included lump sum transfers with exactly one transfer). All other transfer schedules, ranging from five weekly transfers to six quarterly transfers, are considered stream transfer programs.

Gender targeting: We construct a categorical variable that identifies whether programs target UCTs to men, women, or neither. For programs that give cash to households, we only consider a program to target females (males) if it ensures the cash transfer is delivered to a woman (man) in the household.⁵ We do not define a program as targeting females (males) if it allows households to choose who receives the transfer, even if recipients are largely women (men). For programs that give cash to individuals, we say a program

⁵There are no programs in the sample that target males in this manner.

targets females (males) if greater than 80% of the individuals in the sample are women (men). Of the 72 programs in our sample, 32 target women, 6 target men, 28 have no targeting, and 6 randomize targeting to men or women.

Child and food security framing: By definition, UCT programs neither place conditions on how recipients spend the transfer nor require certain behavior as a condition for receiving the transfer. Nonetheless, certain programs in our sample use framing devices to encourage the cash transfer to be directed towards particular ends. These devices vary from a simple labeling of the UCT (e.g., "Child Grant Program," "Hunger Safety Net Program," etc.) to free (voluntary) information sessions on related topics such as education or child nutrition. We construct a binary indicator variable that identifies programs using framing related to food security or child development, including maternal health, child nutrition, and education.⁶

Total transfer amount and monthly tranche amount: We employ two measures for the size of the transfer, the total amount transferred and the monthly tranche amount. The definition of the total transfer amount is straightforward: the sum of the value of all transfers made to program beneficiaries by the time of the endline survey, as in Kondylis and Loeser (2021) (if individuals varied, we report the average each recipient received in total).

The second measure, the monthly tranche amount, is equal to the total transfer amount divided by the number of months since the first transfer. For ongoing stream transfers, this measure is equivalent to the monthly transfer amount (if ongoing stream transfers are not monthly, we convert the amount to the average monthly transfer amount). For completed stream transfers and lump sum transfers, we take the sum of all transfers made and divide by the number of months since the first transfer; this thus facilitates comparing to ongoing stream by using a monthly tranche amount that corresponds to what would

⁶See Appendix Table A.3 for a complete description of targeting and framing across all programs in the sample, including framing related to goals other than improving child welfare or food security.

have been transferred had the same total been spread over the full time period from first transfer to measurement (i.e., just like the ongoing stream programs). All transfer amounts are then converted to 2010 USD PPP.

We do not include estimates for stock outcomes (e.g., assets, anthropometrics) when using the monthly tranche amount, because this would be confounding the tenure of the program with the monthly transfer amount, rendering results difficult to interpret. Similarly, for lump sum transfers, while we do estimate the impact using the monthly tranche amounts in order to compare to stream transfers, we consider the total transfer amount to generate the more interpretable estimate.

Treatment effects: We extract treatment effects directly from the papers' results tables rather than using the studies' underlying data. This approach means that we cannot ensure that our estimates come from identical regression specifications. It has the advantage, however, of being faster to produce and allows inclusion of both older publications from before norms of data publication were more widespread and newer papers (e.g., working papers) for which data are not yet available.

While we cannot guarantee regressions specifications are perfectly consistent across studies, we prefer estimates from regressions that disaggregate by survey round and treatment arm and that contain fewer control variables.⁷ Outcomes are converted to 2010 USD PPP. Flow variables, such as consumption and income, are converted to common periods of time (i.e. per month or per week). Psychological well-being and food security outcomes are standardized, if necessary, by dividing by the control group standard deviation.⁸ Once converted to appropriate units, we divide all treatment effects by the total transfer amount or monthly tranche amount to construct the outcome variables standardized relative to the transfer amount, thus allowing results to be interpreted as the treatment effect per

⁷See Appendix for a complete description of our preferred specifications.

⁸See Appendix for a complete description of how each outcome variable is converted to common units. Appendix Tables B.1 and B.2 also present the treatment effects on food security and psychological well-being outcomes before and after standardization.

dollar transferred. We typically scale treatment effects by \$100 or the median transfer amount of the programs in our sample.

Months since program onset: Short-term and long-term effects: We extract the average number of months between the first transfer (not the baseline survey) and the endline survey. Figure 2 visualizes the temporal distribution of our data for each of the outcomes⁹. If a study does not report time since first transfer, we infer timing from the program's scheduled timeline. We consider a treatment effect measured at an endline up to 18 months after program onset to be a short-term effect. All treatment effects measured more than 18 months after program onset are consider long-term effects. Note a program may administer one follow-up survey one year after program onset and another follow-up two years after program onset. Results from the first follow-up are considered short-term and the second are long-term.

Months since program completion: Ongoing and completed programs: We also extract the average number of months since last transfer, as for months since first transfer. We consider a UCT program ongoing if the number of months since last transfer is equal to zero or if transfers are still being administered to participants at the time of survey. If the number of months since last transfer is greater than zero and the final transfer of the program has been delivered, we consider a program completed. Note, all lump sum programs are completed programs. Several of the UCT programs in our sample are large government-run social protection programs that administer stream transfers indefinitely. While participants may flow in and out of the program over time due to changing eligibility status, we generally do not have information on the proportion of RCT participants still receiving transfers at endline. We thus consider these programs ongoing. Combining completion status (ongoing vs. completed) with transfer frequency (stream vs. lump sum), our subsequent analysis considers three disbursement schedules: ongoing stream programs, completed stream programs, and lump sum transfer programs.

 $^{^{9}\}mathrm{Appendix}$ Table C presents the distribution of months since first and last transfer, broken down by disbursement schedule type

3 Methodology

A crucial methodological challenge in any meta-analysis based on RCTs is how to best aggregate information from multiple studies to estimate a measure of the general effect of the treatment with credible external validity. An individual RCT can provide a consistent estimate of the average treatment effect of cash transfers on a given outcome in a particular population during a specific time period and context. But how much of the estimate is due to idiosyncratic elements of the context (e.g., political instabilities, natural catastrophes, implementation fidelity, etc.) and how much due to statistical regularities with generalizable external validity (e.g., consumption increases from cash transfers are stronger in lower income samples)? In the following, we lay out key characteristics of our model and estimation method, as well as regarding the assumptions we make with respect to the generative process of the data and our statistical framework.

3.1 Hierarchical Linear Models for Meta-Analysis

Assume a researcher has gathered N estimates TE of average treatment effects (ATEs) from comparable RCTs with corresponding standard errors SE and a set of RCT-level covariates X (e.g. whether the transfer schedule is a stream or a lump sum). The researcher is not only interested in understanding the common evidence of a statistically significant effect across RCTs, but also in identifying if certain features of the interventions correlate with higher or lower effects. Assume that the data generating model follows a linear hierarchical structure of the following nature:

$$\hat{TE} \mid \theta \sim \mathcal{MN} \left(\theta, \begin{bmatrix} \hat{s}e_1^2 & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & \hat{s}e_N^2 \end{bmatrix} \right)$$
$$\theta \mid \beta, \sigma_\theta \sim \mathcal{MN} \left(X\beta, \ \sigma_\theta^2 I_N \right)$$
$$\{1, ..., K\} \quad \beta_k \sim \mathcal{N}(0, 25)$$

 $\forall k \in$

$$\sigma_{\theta} \sim \mathcal{H}alf - \mathcal{N}ormal(0, 25).$$

The interpretation of the model is that treatment effect estimates are drawn from distinct and conditionally independent distributions centered around a parameter θ with variances corresponding to their empirical estimates \hat{SE}^2 , which are supposed to be consistent estimators of the former. Crucially, these parameters come from a common distribution with a common mean and standard deviation, i.e. $\mathcal{N}(X\beta, \sigma_{\theta}^2 I_N)$. The model is a generalization of the classical Rubin (1981) model, a simple random effects model, in line with a growing literature that uses more complex formulations to uncover dynamic effects of treatment or subgroup heterogeneity (e.g. Kondylis and Loeser (2021), Alley (2022), Bandiera et al. (2021)). Here, θ is not centered around a common mean but instead around an expectation depending on an RCT-specific set of covariates with constant additive and linear effects. This allows us to aggregate information across studies, while also estimating parameters that characterize the underlying heterogeneity across RCTs. We outline the different specifications we use for the distribution of $\theta \mid \beta, \sigma_{\theta}$ in subsection 3.3.

We choose a random effects model specifically to avoid the much stronger assumption of no true heterogeneity inherent in fixed effects models. Fixed effects models assume that each estimate is an independent draw from a common distribution such that variation in estimates results exclusively by sampling variation (Rubin 1981). Study-level effects are modeled as measurements of a common effect plus some sampling error, either using the underlying data or an estimator of the treatment effect of choice (Borenstein et al. 2010). Examples of fixed effects models include taking the average of the estimates weighted by the inverse of their estimated variance (e.g. Kondylis and Loeser (2021)) or running a pooled regression using all the underlying RCT-level data and controlling for study fixed effects (e.g. Banerjee, Duflo, et al. (2015)).

On the other hand, random effects models in the tradition of Rubin (1981) allow for non-sampling based heterogeneity in treatment effects across RCTs by introducing a hierarchical structure. Single estimates are assumed to be sampled realizations from distinct distributions (i.e. the first hierarchical layer) whose central parameters come from a common distribution (i.e. the second hierarchical layer). This permits us to both control for the sampling variability of the estimates and identify their idiosyncratic heterogeneity. In line with previous work (e.g. Raudenbush and Bryk (1985), Vivalt (2020)), we assume a hierearchical additive model, allowing the heterogeneity across RCT-estimates to vary across a set of study-level covariates and thus making less stringent assumptions, while potentially uncovering what features of the interventions correlate with higher average treatment effects (Meager (2019) and Meager (2022)).

3.2 Bayesian Estimation

The next challenge is estimating our data generating model, by choosing a suitable statistical approach. The Bayesian approach naturally fits such a data structure and can be flexibly implemented by relying on the assumption of exchangeability (a strictly weaker assumption than independence). Under this assumption, the data are independent conditional on a set of parameters (De Finetti 1972). In our model we assume conditional exchangeability, as we characterize the second layer distribution to depend on a set of covariates (X) and parameters (β) . This assumption means that, conditional on the RCT features that we consider, observations can be permuted across contexts, without affecting their joint probability distribution.

As previously outlined, Bayesian additive hierarchical models have been widely adopted in the meta-analytical literature in Economics (Burke et al. 2015, Meager 2019, Vivalt 2020, Bandiera et al. 2021, Alexander et al. 2021, Meager 2022, Noam Angrist 2023) and in other disciplines (e.g., Chu et al. 2009, Heeg et al. 2023, Liu et al. 2017). As Raudenbush and Bryk (1985) notice, this approach is formally of an Empirical Bayes nature since we use the data (i.e. \hat{se}) to inform the likelihood distribution. This combines advantages from both the Frequentist and the Bayesian frameworks. On one hand, Frequentist asymptotic distributional results guarantee that each estimate of an average treatment effect is asymptotically Gaussian. This renders the choice of the likelihood less restrictive (A. B. Gelman et al. 1995, Noam Angrist 2023) since it hinges on the same assumptions that render legitimate the Frequentist inference of the original papers.

Frequentist estimation techniques such as maximum likelihood (MLE), on the other hand, condition on the modal point estimate of the higher layers' parameters and thus do not take into account their posterior uncertainty, on the other hand Bayesian techniques sample the parameters from their own estimated posterior distribution, thus taking into consideration a wider range of possible values. (A. B. Gelman et al. 1995, Chapter 5). Moreover, priors can help improve the stability of estimates by providing what is known in the Frequentist framework as regularization (A. Gelman et al. 2017, Hastie et al. 2001). Regularization, a Frequentist technique, can help reduce the variance of estimates and focus the estimation on regions of the parameter space that are relevant (e.g. away from treatment effects of exaggerated magnitude), at the cost of introducing some bias. This can render estimates more precise than with MLE or inappropriately flat priors (A. Gelman et al. 2017). Indeed, Stegmueller (2013) finds that, in simulation studies of additive hierarchical models, MLE tends to have both more severe finite sample bias and/or lower confidence interval coverage, the latter being exacerbated when the number of hierarchical groups (that is, in the meta-analytical context, the sample size itself) is smaller.

The numerical estimation of the model is conducted using Stan (Stan 2022), a software for Bayesian simulations, that uses a Hamiltonian Monte Carlo procedure (Betancourt 2020) to explore posterior density distributions using gradients. This approach allows for flexible definitions of priors and to estimate even relatively complex models.

3.3 Model Specifications

Throughout our analysis, we estimate increasingly richer and more general versions of $\theta \sim \mathcal{N}(X\beta, \sigma_{\theta}^2 I_N)$ by expanding the set of covariates in X.

We start from the original Rubin (1981) random effects model:

(1)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_1 \mathbf{1}, \ \sigma_{\theta}^2 I_N \right)$$

Building on Equation (1), our second model allows for heterogeneity with respect to the type of the transfer and the time of measurement of the effect. The type is defined by the disbursement schedule of the RCT, i.e. whether the transfer was delivered as a lump sum (L) or a stream (S); the timing of measurement, which is relevant only for stream transfers, is whether the programs were completed (CS for "completed stream") or ongoing (OS for "ongoing stream") at the time of measurement:

(2)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_1 L + \beta_2 CS + \beta_3 OS, \ \sigma_{\theta}^2 I_N \right)$$

In the subsequent version of our model, we build further on Equation (2) adding covariates

for the number of months since first or last cash transfer (M) and the squared value of this term to estimate the temporal dynamics of treatment effects. We allow for heterogeneity in dynamic effects between ongoing streams and completed programs (i.e., both completed streams and lump sum transfers). Note that the interpretation of the two trends differs: for completed interventions (C), we estimate a dissipation effect after payments end $(M \odot$ $C+M^2 \odot C)$. For ongoing streams, we estimate a multiplicative effect $(M \odot OS+M^2 \odot OS)$, such as when an individual saves or invests part of the tranche and so can collect interest, additional revenues, and can make further investments in assets:

(3)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N}(\beta_{1}L + \beta_{2}CS + \beta_{3}OS + \beta_{4}M \odot C + \beta_{5}M^{2} \odot C + \beta_{6}M \odot OS + \beta_{7}M^{2} \odot OS, \sigma_{\theta}^{2}I_{N})$$

One drawback of Equation (3) is that it takes a considerable amount of observations to estimate a dynamic trend with precision and, even though our sample for total consumption is sizable for the standards of meta analyses, it might still lead to imprecise measurements. Therefore, as a further complementary estimation we specify a model where we discretize the dynamic dimension of our observations into two categories: short run measurements from up to 18 months from the first transfer and long run measurements after 18 months. The resulting specification of the model is the following, denoting short run by ST and long run by LT:

(4)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N}(\beta_{1}ST \odot L + \beta_{2}LT \odot L + \beta_{3}ST \odot C + \beta_{4}LT \odot C + \beta_{5}ST \odot OS + \beta_{6}LT \odot OS, \ \sigma_{\theta}^{2}I_{N})$$

The disadvantage of this model is that it loses some information in discretizing the dynamic dimension of our dataset, however it is able to detect average differences between short term and long term measurements of average treatment effects more robustly, since it does not rely on a specification of such underlying decaying or accumulation effects, which might have small sample noisy estimates.

We also want to test for decreasing marginal returns for transfer amount, taking into consideration the disbursement type. For ended interventions, we are interested in estimating the marginal effect of a higher total amount transferred, hence, starting from Equation (2), we augment the model with the total amount transferred in PPP interacted with an indicator for the program being either a lump sum transfer or and ended stream $(TT \odot C)$. On the other hand, for ongoing stream transfers, we are interested in estimating the effect of a marginal increase in the monthly tranche and so we run a different model by adding monthly tranche interacted with an indicator for ongoing stream transfer $(MT \odot OS)$. The two specifications are the following:

(5)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_1 L + \beta_2 CS + \beta_3 OS + TT \odot C, \ \sigma_{\theta}^2 I_N \right)$$

(6)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_1 L + \beta_2 CS + \beta_3 OS + MT \odot OS, \ \sigma_{\theta}^2 I_N \right)$$

The last dimension of heterogeneity we choose to investigate is whether targeting the transfers by gender or labelling it as for children or food lead to differential effects. In order to do this, we go back to a simpler model: let T denote whether the transfer was targeted to women and F if it was framed for children, then the previous model becomes:

(7)
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_{1}T + \beta_{2}(1-T), \ \sigma_{\theta}^{2}I_{N} \right)$$
$$\theta \mid \beta, \sigma_{\theta} \sim \mathcal{N} \left(\beta_{1}F + \beta_{2}(1-F), \ \sigma_{\theta}^{2}I_{N} \right)$$

4 Results

Table 3 presents average treatment effects in the full sample, estimated using Equation (1). Panel A displays the predicted treatment effect of a \$100 total transfer amount, our preferred outcome variable for estimating impact of lump sum transfers, while Panel B displays the predicted treatment effect of a \$100 monthly tranche amount, our preferred outcome variable for stream transfers.

Tables 4 examines heterogeneity by disbursement schedule, i.e., by ongoing streams, completed streams, and lump sums, estimated using Equation (2). In Table 5, we show dynamic treatment effects on monthly household consumption estimated using Equations (3) and (4). In Table 6a, we estimate the curvature of effects with respect to transfer size, i.e. whether there are decreasing, increasing, or constant marginal returns to cash using Equations (5) and (6). Tables 7 and 8 analyze the impact of targeting by gender and framing by food security and child development goals, based on Equation (7). Finally, Table 9 presents benefit-cost ratios under different assumptions (regarding duration of stream transfers and program costs) and specifications (estimating dynamic effects as binary estimates for under or over 18 months versus a quadratic specification).

4.1 Do Cash Transfers Shift Labor Supply and Income?

UCTs generate positive impacts on income, with credibility intervals considerably removed from zero, thus clearly rejecting "dependency" theories that predict negative impacts on income. Specifically, Column 1 of Table 3 shows positive impact on monthly income for both total transfer (\$1.4/month per \$100, 95% CI: 1.0, 1.9) and the monthly tranche amount (\$22.6/month per \$100, 95% CI: 15.4, 30.6).¹⁰ ¹¹ Results are qualitatively similar in Table 4, in which we disaggregate estimates by disbursement schedule into ongoing streams, completed streams, and lump sum transfers.

Results on income are further supported by positive effects on labor force participation (LFP). Table 3 shows that UCTs increase LFP by 4.4 percentage points (95% CI: 2.2, 6.6) predicted at the median total transfer amount, and by 5.6 percentage points (95% CI: 2.1, 9.2) predicted at the median monthly tranche amount.¹² Table 4 further breaks down the analysis by disbursement schedule and shows consistently positive point estimates. With fewer studies per estimate, however, several of the credibility intervals include zero.

We also see positive, but less robust, results on total hours worked. The point estimates are positive for both methods (total transfer and monthly tranche) but the 95% credibility interval includes zero for total transfer but is strictly above zero for monthly tranche. Specifically, Table 3 reports an increase of 0.4 hours per week (95% CI: -0.4 to 1.2) for the median total transfer amount and 0.2 hours per week (95% CI: 0.012 to 0.447) for the median monthly tranche amount. Table 4, which further disaggregates by disbursement schedule, finds even wider intervals. However estimates are from as few as two programs, and at most seven, so we draw little to no inference from the analysis on differential impact by disbursement schedule on hours worked.

¹⁰To construct the sample of treatment effects on monthly income, we use measures of total individual or household income when reported or the largest sub-category of income (e.g., wage earnings, household enterprise profits, etc.) available when total income is not reported.

¹¹Appendix Table D.1 reports treatment effects on alternative measures of income, including a sample that just uses estimates on total individual or household income; predicted treatment effect sizes based on this sample are slightly larger than the effects we report in Table 3. Also, note that papers vary in their reporting of treatment effects on income at the individual or household level. We do not adjust for this inconsistency, which reflects a limitation of relying on estimates extracted directly from papers rather than using the studies' underlying data.

¹²These large effects are in part driven by two positive outliers (in a sample of only 17 estimates) from the Child Development Grant Programme in Nigeria which finds a \$20 monthly stream transfer (about half the sample median of \$35) to increase paid work among wives in treatment households by 6.0 percentage points after 24 months and 10.7 percentage points after 48 months. The same program raised female labor force participation by 30 and 53 percentage points per \$100 monthly tranche at months 24 and 48, respectively.

Taken together, cash transfers consistently generate positive impacts on our thirteen main outcomes, and at worst, we can rule out meaningfully negative impacts. These results are consistent with the analysis in Banerjee, Hanna, et al. (2017), which examines seven studies (six conditional cash transfers and one UCT) and documents predominantly positive and at worst null results.

4.2 Investment and Consumption Patterns

Next we examine the impact of UCTs on investment and consumption, and patterns observed across disbursement schedule and over time. We find support for the ofthypothesized result that stream transfers generate more change in consumption relative to lump sums, and vice versa for investments or durable goods.

Transfer recipients trade off spending on consumption goods (durable or non-durable) and investing in productive assets. We find positive effects across the board on both consumption and investment. Table 3 reports a \$14.7 (95% CI: 10.6, 18.9) increase in monthly total household consumption for the median total transfer amount and a \$18.6 (95% CI: 13.6, 23.9) increase for the median monthly tranche amount. The majority of the consumption increase comes from food: \$12.3 (95% CI: 8.9, 16.0) increase in monthly household food consumption for the median total transfer amount and \$16.4 (95% CI: 12.1, 21.0) for the median monthly tranche amount. The stock of total assets increases by \$19.4 (95% CI: 12.4, 26.7) for each \$100 of the total transfer amount.

Transfer frequency and timing of the endline measurement relative to program completion drive heterogeneity in consumption and investment behavior. Specifically, completed stream programs produce results similar to lump sum transfers but different from ongoing stream programs. Table 4 Panel A reports similar point estimates regarding the treatment effect per total transfer amount for household consumption across all three disbursement schedules, with ongoing streams having a marginally higher effect than the other two. However, when analyzed per monthly tranche amount (Panel B), the treatment effects on consumption are notably stronger for ongoing streams. This is likely the consequence of recipients treating ongoing transfers similar to income, resulting in a higher marginal propensity to consume. Completed streams and lump sum transfers do not generate the same expectation of future cash and so their impact is driven entirely by savings and potential increases in income from prior additional investments. Specifically, ongoing streams of a \$100 monthly tranche boost consumption by \$69.0 (95% CI: 51.1, 87.9) compared to \$50.1 (95% CI: 22.9, 78.1) for completed stream programs and \$38.8 (95% CI: 22.4, 55.7) for lump sum transfers. Treatment effects per \$100 monthly tranche on monthly household food consumption are as large as \$71.7 (95% CI: 57.4, 87.0) for ongoing stream programs but only \$21.9 (95% CI: 8.6, 36.6) for lump sum transfers and not statistically significant for completed stream programs.¹³

Examining food security, differences between disbursement schedules look less stark.¹⁴ Table 4, Panel B shows that a \$100 monthly tranche yields a 0.8 standard deviation improvement (95% CI: 0.5, 1.2) in food security for ongoing streams, compared to 1.1 for completed streams (95% CI: 0.7, 1.5) and 0.4 for lump sum transfers (95% CI: 0.1, 0.6). We conjecture this inconsistency between impacts on food consumption and food security arises since very small increases in food consumption can have substantial impacts on measures of food security (e.g., of skipping meals, experiencing hunger, etc.) for households near the threshold.

The stock of total assets shows similar differences across disbursement schedules to consumption, with completed streams yielding results more similar to lump sum transfers than to ongoing streams. Specifically, for each \$100 total transfer, completed streams and lump sum transfers generate increases in total assets of \$26.0 (95% CI: 12.1, 40.0) and \$21.5 (95% CI: 12.6, 30.8), respectively, while ongoing streams yield no statistically

¹³Note, however, that data limitations are severe for completed stream programs: Only three such programs report food consumption.

¹⁴Since we use z-scores, we show in Appendix Table B.1 a complete list of treatment effects on food security measures before and after standardization.

significant increase (\$1.5; 95% CI: -15.6, 18.7). In contrast, the increase in the stock of financial assets is not statistically significant for completed streams, whereas ongoing streams increase financial assets by \$2.4 (95% CI: 0.9, 4.0) for each \$100 of the total transfer amount, and for lump sum transfers increases by \$1.6 (95% CI: 0.8, 2.5). Estimates based on the amount of the monthly tranche yield qualitatively similar results across disbursement schedules.¹⁵

Beyond sizable effects on direct economic measures, such as consumption, income, and assets, UCTs also meaningfully improve psychological well-being. Table 3, Column 2 reports a 0.19 standard deviation increase at the median total transfer amount (95% CI: 0.12, 0.26).¹⁶ The positive average treatment effect on psychological well-being is primarily driven by ongoing stream UCT programs (Table 4), i.e., even though economic impacts persist, the psychological well-being impacts dissipate more rapidly. Ongoing stream UCTs improve subjective measures of well-being by 1.1 standard deviations per \$ 100 monthly tranche (95% CI: 0.7, 1.5). These large estimates are partially driven by three positive outliers from the Zambia Child Grant Program (CGP). ¹⁷ In contrast, lump sum transfers and completed stream programs produce effects close to zero that are not statistically significant. This is generally in line with the literature on cash transfers and mental health that finds more modest ameliorating effects on subjective well-being in combined samples of CCTs and UCTs (McGuire et al. 2022) and depression (McGuire et al. 2022; Wollburg et al. 2023).

¹⁵Appendix Table D.2 reports treatment effects on various types of assets: durable assets, productive assets, and financial assets. However, we do not have sufficient data to conduct meaningful comparisons of impact by disbursement schedule on these disaggregated outcomes.

¹⁶See Appendix Table B.2 for a complete list of treatment effects in our sample on outcomes related to psychological well-being before and after standardization.

¹⁷When we exclude three outliers that originate from the Zambia Child Grant Program (CGP), the treatment effect per \$100 monthly tranche is still strongly positive, but reduced from 0.5 standard deviations (95% CI: 0.3, 0.7) to 0.4 (95% CI: 0.3, 0.5) in the full sample or from 1.1 (95% CI: 0.7, 1.5) to 0.6 (95% CI: 0.4, 0.9) in the ongoing streams sample, as reported in Table D.3. The estimates from the Zambia CGP are not only positive outliers, they are also constructed from a binary indicator variable for whether the respondent was feeling happy or happier than 12 months prior. We do not extract an equivalent outcome variable to construct our standardized outcome for any other program. Appendix Table B.2 reports all treatment effects on psychological well-being before and after standardization.

4.3 Dynamic Effects

Next we examine temporal dynamics. Considering the timing of impact assessment relative to program onset and completion offers further insight into patterns of consumption and investment behavior by program type. In Table 5, we explore the dynamic impacts on total monthly household consumption over time. We choose to focus on this outcome for substantive and practical reasons. Total household consumption is an aggregate measure of economic well-being. With 82 estimates, we have more observations than nearly any other outcome and thus more ability to estimate dynamic effects by disbursement schedule. Also, our sample of reported treatment effects on household consumption is relatively balanced between ongoing stream, completed stream, and lump sum programs. In addition to consumption, we examine dynamic effects on the stock of total assets, in order to shed light on savings and investment behavior not fully captured by consumption. With a smaller sample, however, we are less able to draw robust conclusions.

Our analysis reveals little evidence that treatment effects dissipate over time. In fact, the benefits of ongoing stream UCTs appear to grow. This suggests that while transfers continue some funds get consumed and others invested, leading to increasing income over time that feeds back into consumption. We do, however, note suggestive evidence of smaller consumption effects for lump sum transfers in the long run. Figure 3.1 plots the posterior average treatment effects on total consumption sorted by months since first transfer to visualize the relationship between effect size and measurement timing.

As seen in Table 5, Panel B1, we find evidence that the effects of ongoing stream transfers on household consumption are greater in the long run (18 months after transfer onset). The long-term treatment effect per \$100 monthly tranche is \$98.8 (95% CI: 76.4, 121.5) while the short-term treatment effect per \$100 monthly tranche is \$38.5 (95% CI: 18.0, 60.3).¹⁸ For completed stream programs and lump sum transfers, we do not observe

¹⁸Note this finding is not robust to our alternative outcome variable definition, as seen in Panel A1 of Table 5. While we still estimate a larger long-term treatment effect, the credibility intervals of our

statistically significant differences between short-term and long-term effects.

Panels A2 and B2 of Table 5 present results from a polynomial model which interacts a continuous months variable and its squared term with ongoing and completed program indicators.¹⁹ Consistent with our findings in Panels A1 and B1, we observe greater consumption effects over time for ongoing stream programs but virtually no dynamic effects for completed stream programs and lump sum transfers. The predicted treatment effect of a \$100 UCT stream at month 12 is \$43.2 (95% CI: 24.0, 63.6) and at month 24 is \$91.8 (95% CI: 69.1, 115.3). The coefficients on the months and months squared covariates, however, are not statistically significant.

4.4 Curvature with respect to transfer amount

Whether UCTs exhibit increasing marginal returns is not only a key question for economic theory but also a critical policy question. If there are increasing marginal returns beyond a certain threshold, then this may justify giving larger sums of cash to a small number of recipients to push them out of a poverty trap. Whereas if there are diminishing returns, then policymakers should give smaller transfers to many more recipients. The line of thinking, however, ignores other moral considerations, such as equity, and practical concerns, such as the interaction between transfer size and administrative costs

Figure 3.2 plots the posterior average treatment effects on total consumption sorted by monthly tranche amount to visualize the relationship between the treatment effect per dollar and transfer size. The forest plot indicates no clear pattern of increasing or decreasing marginal returns. In Table 6a, we test explicitly for increasing or decreasing marginal returns to UCTs by incorporating covariates for transfer size interacted with

estimates largely overlap.

¹⁹Due to the limited number of estimates for completed stream programs and the fact that the dynamic effects of completed stream programs appear more similar to lump sum transfers than to ongoing stream programs as shown in Panel A1, we pool completed stream programs and lump sum transfers to estimate the coefficients on the months and months squared terms.

disbursement type into our model. Since our outcome variable is the treatment effect per dollar transferred, the interpretation of the coefficient on these covariates is equivalent to the second derivative of the treatment effect (i.e. curvature) with respect to transfer amount. For all disbursement types, we find negative (i.e., concave) but not statistically significant curvature effects on monthly household consumption for any disbursement type.

Thus we do not find evidence for "threshold" poverty trap models, at least for thresholds within the range of transfer amounts where our evidence is robust. But absence of evidence is not evidence of absence, particularly in this case, as this is a fairly weak test for the poverty trap theory given this is examining patterns at the study-level across markets and countries, rather than a household-level micro examination that attempts to incorporate household level heterogeneity which inevitably affects any such threshold.

We find mixed evidence of curvature when examining total assets. Columns 4-6 report these results. Note that only lump sum has a large sample of studies (41 estimates from 23 programs) and finds a slightly positive (but neither large economically nor significant statistically) estimate for the squared-term (20th to 80th percentile shifts from 21.1 to 21.3). However ended streams (which has only 12 estimates from 4 programs) does yield statistically significant and economically meaningful decline in marginal returns to increases in the magnitude of stream transfers that have ended (20th to 80th percentile shifts from 44.2 to 26.3).

To further examine this question of convexity or concavity with respect to grant size, Table 6b presents the curvature estimates results from each of the studies which randomly assigned individuals to different grant amounts. Column 5 reports the ratio of the transfer sizes tested within each study. Column 6 reports the ratio of the treatment effects on consumption for the different grant amounts within the study. And thus Column 7 is then the ratio of the ratios, such that > 1 indicates increasing returns to grant size (convexity) and < 1 indicates decreasing returns to grant size (concavity). Column 8 then reports the analogous estimate from our model (using the model specified in Table 6a). The estimates for study-specific ratios range from 0.23 (quite concave) to 5.29 (quite convex), but the half of the estimates (9 of 18 rows) are between 0.70 and 1.05. Column 8 then shows the model estimates as predicted by our Bayesian analysis, which as expected from the Table 6a estimates are typically near and below 1. Columns 9, 10, and 11 then show the same, but for stock of total assets. Here Column 10 shows that there is higher variance across studies with respect to whether there is concavity or convexity, whereas the estimates from the model are almost exactly linear for lump sums, and slightly concave for completed streams.

4.5 Targeting and Framing Effects

In Table 7, we report on the differential impact of programs targeted to women (versus to men or non-targeted). We consider a program targeted to women (men) if the cash is intentionally given to women (men) exclusively or if greater than 80% of the intended recipients are female (male). Programs targeted to women produce greater consumption effects than programs without any gender targeting: Female-targeted UCTs lead to a \$4.4 increase per \$100 total transfer amount in monthly total household consumption (95% CI: 3.4, 5.5) compared to a \$2.0 increase per \$100 total transfer amount (95% CI: 1.1, 2.8) for non-targeted programs. This difference appears to driven primary by greater food consumption. Female-targeted transfers on average also generate considerably larger treatment effects on income than non-targeted programs: \$1.9 per \$100 of total transfer (95% CI: 1.2, 2.5) versus a 95% credibility interval of 0.4 to 1.4 for non-targeted UCTs.

Other results do not differ between targeting categories, with credibility intervals overlapping substantially for treatment effects on child welfare outcomes, such as heightfor-age (HAZ), weight-for-age z-scores (WAZ), and school enrollment, which may be a consequence of the imprecision of our estimates. As there are very few male-targeted programs, we generally lack the ability to credibly distinguish differences between male-targeted programs and female-targeted or non-targeted programs for any outcomes. The exception is income, where we have relatively more data on male-targeted programs. Here we observe larger effects for male-targeted programs than either non-targeted or female-targeted programs.

In Table 8, we compare impacts from programs that employ framing to encourage spending on children or food and programs without such framing. In Panel A, we find point estimates for framed transfers are larger and outside the 95% credibility interval for non-framed for four outcomes: food consumption, food security, income, and psychological well-being. Findings from our monthly tranche specification in Panel B are similar, with even more stark differences for food consumption and food security z-scores. These results suggest that framing improves food-security related outcomes, but we do not find credible evidence that it has any positive effect on child-related outcomes, such as HAZ, WAZ, and school enrollment.

4.6 Benefit-Cost Analysis

We construct two simple models of future cash flows to estimate the returns to UCTs and compare the relative benefits of various program designs. Similar to Blattman et al. (2016), we define benefits as the predicted treatment effects on consumption and costs as the total transfer amount, discounting all values to the first month of the program using a 5% discount rate. Our approach, however, adds a layer of sophistication by leveraging our dynamic effects results.

We present the results of our benefit-cost analysis in Table 9. In Panel A, we display benefit-cost ratios (BCRs) from a binary dynamic effects model which, using our estimates from Panels A1 and B1 of Table 5, assumes short-term treatment effects last until month 18 and long-term treatment effects persist thereafter. Assuming 24% administrative costs, this model estimates a BCR of 3.3 for lump sum transfers or 1.5 - 4.2 for stream programs of varying duration.

Our dynamic effects binary model will overestimate the impact of UCTs if the longrun benefits in fact deteriorate more rapidly than the 5% discount rate. The dynamic effects polynomial model attempts to address this shortcoming. Using estimates from Panels A2 and B2 of Table 5, this model assumes that benefits amplify as transfers are ongoing and dissipate once transfers are completed.²⁰ Accounting for 24% administrative costs, we find that lump sum transfers yield a BCR of 0.8 while stream programs lasting 12 to 48 months yield BCRs ranging from 0.7 to 1.2. Longer stream programs prove more cost-effective despite higher costs due the amplification effect of ongoing streams.

5 Conclusion

The large-scale expansion of randomized evaluations over the past several decades provides an opportunity for pooling information across evaluations to make important contributions both to policy and to the adjudication of whether or not the empirical lessons from evaluations are robust. Cash transfers are an especially well-suited type of intervention for such an exercise, because the degrees of intervention variation are more limited and the implementation fidelity is easier to define and less likely to vary and drive results. We therefore conduct a meta-analysis based on 114 studies from 72 randomized evaluations.

We present two layers of main results. First, for the average effects, we find positive and strong average treatment effects on a wide range of outcomes, and irrespective of whether transfer frequency is lump-sum or stream: consumption, income, labor force participation, school enrollment, food security, psychological well-being, assets, and child

²⁰Our model predicts that benefits fall to zero approximately 8 years after transfers end.

height-for-age. Monthly household consumption increases by \$69 per \$100 monthly transfer in response to ongoing stream programs and by \$2.2 per \$100 transferred (i.e., a 26% annualized social return on investment) in response to lump sums. Monthly income improves by \$29.8 per \$100 monthly tranche for ongoing stream transfers and by \$1.6 per \$100 total transfer for lump sums. Furthermore, we find similarly strong impacts in the long run (18-48 months) as well as short run (0-18 months), although the impacts dissipate partially if transfers stop and amplify if transfers continue (i.e., ongoing stream transfers are partially consumed and partially invested, leading to larger long-run than short-run impacts). Lastly, we demonstrate that UCTs encourage or at worst do not lower labor supply, contradicting "dependency" theories that cash transfers discourage work.

Second, key elements of program design generate substantial impact variation. UCTs targeted to women have larger impacts on consumption and income than non-targeted programs (although transfers targeted to men generate even higher impact on income yet smaller impacts on consumption, but also are derived from only four programs as compared to 16 and 19 programs for female-targeted and untargeted, respectively). There is also evidence that accompanying UCTs with child-focused framing may improve outcomes related to food security.²¹ Furthermore, considering transfer frequency and timing relative to program completion proves critical to understanding households' consumption and investment response to cash transfers. Ongoing stream transfers produce larger consumption effects while completed stream programs and lump sum transfers facilitate greater asset accumulation. Impacts on income are similar regardless of disbursement schedule.

The fact that lump sum cash transfers spur gains in consumption and income compa-

²¹While we do not include conditional cash transfers (CCTs), other meta-analyses have, and find for example that CCTs increase primary and secondary school enrollment by 1.6 percentage points (95% CI: 0.9, 2.4) and 3.5 percentage points (95% CI: 2.4, 4.6) per \$100 total transfer amount, respectively (Baird et al. 2014). This is larger than our estimate of 0.9 percentage points (95% CI: 0.5, 1.4) on overall enrollment. Baird et al. 2014 also directly compares CCTs to UCTs, estimating larger but not statistically significant marginal impacts of conditionality. Studies investigating anthropometric outcomes find conditionality limits improvements in child weight but has no effect on height (Manley, Balarajan, et al. 2020; Manley, Alderman, et al. 2022).

rable to streams that have ended contradicts the common intuition that lump sums should have a "comparative advantage" in facilitating productive investment. One possibility is that, when assured of a continuing stream of cash transfers, poor households are adept at transferring resources across time to take advantage of investment opportunities. This suggests further analysis that explores heterogeneity in outcomes with respect to access to quality savings opportunities may be a fruitful avenue. This could motivate the design of cash transfers that combine access to savings with stream cash flows, an increasingly easy and low-cost add-on, given the expansion of mobile money. A second possibility is that lump sum transfers create in a sense too much slack, and the marginal dollars are not spent efficiently. This could be due to other market frictions leading to rapidly diminishing marginal returns or due to psychological mechanisms such as cognitive scarcity (see, Mullainathan and Shafir 2013).

We further highlight two important cross-cutting lessons from the data. First, treatment effects appear to be constant over time, which given our data is best understood as up to 48 months after the onset of transfer. This is broadly in line with McGuire et al. (2022) which finds that effects on subjective well-being and depression dissipate at modest rates. There is a clear need for more long-term, follow-up data (Bouguen et al. 2019). Further follow-ups would help trace out potential dissipation or augmentation effects, as most data on lump sum transfers are collected 12 to 48 months after treatment.

Second, we find fairly constant marginal returns with respect to transfer size. The coefficients on the squared term for transfer size is precisely estimated and close to zero, and we do not have the power to estimate functional form more precisely. This null effect is not consistent with "threshold" poverty trap models with large indivisible goods that assume expanding returns. However, with such thresholds inevitably differing across people and markets (or perhaps being above the transfer sizes tested), we cannot rule out asset-based threshold models of poverty.

We close with three methodological considerations that limit how much one can learn from a meta-analysis of this style. First, with respect to many of the most interesting questions, our analysis is severely constrained by not incorporating household-level data. We lack sufficient variation on many important dimensions that require estimating withinstudy heterogeneity or more detailed re-formulation of outcome variables from raw data in order to sync data across studies. For example, we are largely unable to speak to consumption patterns beyond distinguishing total from food consumption. We are also unable to identify the type of assets recipients tend to purchase as this information is not commonly being collected, in particular not for stream programs. Among other things, this impedes a further investigation into the question as to whether the discrepancy between the positive but more modest effects of lump sum transfers on consumption despite their pronounced effect on total assets is due to investments in unproductive, but potentially welfare-enhancing, types of assets (e.g., furniture, house improvements).

Second, while as discussed above there is a constant push for longer term follow-ups (true not just for cash transfers, but for most development interventions), we suggest that we also need more *immediate* data, data that helps illuminate how transfers get spent. This is particularly true for lump sum transfers, to have clearer understanding of households' immediate consumption and investment decisions upon receipt of funds. This question in general is understudied, and cannot be answered well by merely asking people what they did with the funds (Karlan et al. 2016). Instead, we need more studies that do the first follow-up at about one month, in order to establish the initial changes in outflows that occur because of the receipt of the cash transfer. Then, and particularly if this turned out to be predictable from baseline questions (either broadly generic questions, or intentquestions about what they would want to spend any funds received in the next month), analysis could sort households into likely short-run patterns, to then examine how that then led to longer-run changes for households. Furthermore, an exercise could lead to development of "surrogate" measures, i.e. "predictive" outcomes that can be tracked in the short-run and are good predictors of long-run impact. Validation of such measures would then create opportunities for more rapid-fire learning about how to transfer cash, what messages to include, timing, amounts, etc.

Third, we have a herding cats measurement methods problem. While some standards exist with respect to survey and question design, much variation persists, and is both inevitable and healthy. We do not suggest our community knows the best ways to measure; we want innovation in measurement methods. And some variation in survey methods are a natural and important by-product of contextualizing a survey to a given country, culture, economy, etc. These challenges are exacerbated by inconsistent reporting standards at journals (although this has improved considerably, see Nosek et al. (2015)). But while improved norms and compliance in sharing data and survey instruments help considerably, that does not address the challenge created by the variation in what is actually collected in surveys.

Despite these limitations, we believe aggregating reported point estimates at the study-level sheds important light on several theoretical and policy questions. But, important program, study, and context variables– variables either in hand or easily accessible– could not be included in our preferred specifications due to power considerations. For example, we did not have sufficient variation on modality (mobile money versus cash), or timing within the year (particularly important for farmers). Yet despite the limitations, aggregating results from 114 studies yields important theoretical and policy insights, and also points to specific questions that can and should be tackled with synced micro-level data. Lastly, and perhaps most critically, these estimates can serve as a "cash benchmark": if designing a program to try to improve a specific outcome, this analysis provides an estimate for what a simple cash transfer can deliver.

 Table 1a

 Comparison of Cash Transfer Meta-Analyses Papers

For Baird et al. (2014) and Garcia and Saavedra (2017), the counts represent the number of programs rather than studies because study-level information was not reported. For this study, the sum of the count of lump sum and stream studies in columns 8 and 9 exceeds the total number of studies in column 1 because seven studies report results on both stream and lump sum transfers.

Comparison of Cash Transfer Meta-Analyses							
	(1)	(2)	(3)	(4)			
Meta-analysis	Average total transfer amount	Average follow-up timing	Effect interpretation	Outcomes			
This study	854	19 months since first transfer	Treatment effect (TE) per dollar transferred	Consumption, food security, assets, income, labor supply (adult), psychological well-being, school enrollment, and child development			
Baird et al. (2014)	351 (per year)		Binary TE of receiving UCT	School enrollment, attendance, and test scores			
Baranov et al. (2021)			Binary TE of receiving UCT	Intimate partner violence			
Evans and Popova (2017)			Binary TE of receiving UCT	Temptation goods expenditure			
Garcia and Saavedra (2017)			Binary TE of receiving UCT and TE per dollar transferred	School enrollment and attendance			
Guimarães et al. (2023)	143	13 months since baseline	Binary TE of receiving UCT	HIV testing, treatment, and incidence			
Kabeer and Waddington (2015)			Binary TE of receiving UCT	Labor supply (child and adult), consumption			
Kondylis and Loeser (2021)	963	18 months since first transfer	TE per dollar transferred	Consumption			
Little et al. (2021)	8-75 (per month)		Binary TE of receiving UCT	Child development and child nutrition			
Manley et al. (2022)	83	29 months since baseline	Binary TE of receiving UCT	Child development, child nutrition, and incidence of child illness			
McGuire et al. (2022)	855	23 months since first transfer	Binary TE of receiving transfer with covariate for transfer amount	Psychological well-being			
Wollburg et al. (2023)	773	13 months since last transfer	Binary TE of receiving UCT	Psychological well-being			

Table 1b

Transfer amounts reported in 2010 USD PPP. For this study, we report means across programs in the primary outcomes analysis sample.

 Table 2

 Count of Programs and Estimates by Program Design Features

The sum of lump sum and stream programs in Columns 2 and 3 of Panel A does not always equal the total number of programs in Column 1 because some programs implement both stream and lump sum transfers. Similarly, the sum of estimates in Columns 2 and 3 of Panels B and C does not always equal the total number of estimates in Column 1 because Column 1 includes some additional estimates from regressions that pool across lump sum and stream treatment arms. Also, the sum of stream-ended and stream-ongoing programs in Columns 4 and 5 of Panel A does not always equal the total number of stream programs administer follow-up surveys both as the program is ongoing and after it has ended.

Table 3

95% credibility intervals in parentheses. All currency values are reported in 2010 USD PPP. For lump sum transfers, the monthly tranche amount for Panel B is calculated by dividing the total transfer amount (used in Panel A) by the number of months since the first transfer. Our dataset for **Monthly Household Consumption** uses treatment effects on total consumption when reported; we use treatment effects on non-durable consumption or food consumption when total consumption is unavailable. Our analysis controls for whether food and durable goods are included in total consumption. **Panel C** shows results on Total Household Consumption from a model that does not include these controls. Our dataset for **Monthly Income** uses reported treatment effects on total household or individual income when reported; if treatment effects are only reported by sub-category of income, e.g., wage earnings, non-farm enterprise profits, etc., then the sub-category with the highest control group mean is used instead. See Appendix Table D.1. for a comparison to analysis that only uses reported estimates on total household or individual income.

 Table 4

 Heterogeneous Treatment Effects by Disbursement Schedu

95% credibility intervals in parentheses. All currency values are reported in 2010 USD PPP. Treatment effect per total transfer amount (Panel A) is our preferred outcome variable for completed streams and lump sum transfers. Treatment effect per monthly tranche amount (Panel B) is our preferred outcome variable for ongoing stream transfers. Median monthly tranche amounts are \$36, \$45 and \$44 for ongoing streams, completed streams, and lump sum programs, respectively. Median total transfer amounts are \$652, \$674, and \$651 for ongoing streams, completed streams, and lump sum programs, respectively. Median total transfer amounts are \$652, \$674, and \$651 for ongoing streams, completed streams, and lump sum programs, respectively. Our dataset for **Monthly Household Consumption** uses treatment effects on total consumption when reported; we use treatment effects on non-durable consumption or food consumption when total consumption is unavailable. Our analysis controls for whether food and durable goods are included in total consumption. Our dataset for **Monthly Income** uses reported treatment effects on total household or individual income when reported; if treatment effects are only reported by sub-category of income, e.g., wage earnings, non-farm enterprise profits, etc., then the sub-category with the highest control group mean is used instead. See Appendix Table D.1. for a comparison to analysis that only uses reported estimates on total household or individual income. We do not report results on stunting due to data limitations. Effects with four or fewer estimates have been grayed out.

Predicted Treatment Effects per \$100								
Estimated on Short-Term Estimates (measurement up to 18 months after first transfer) Estimated on Long-Term Estimates (measurement more than 18 months after first transfer)	38.5 (18.0, 60.3) 98.8 (76.4, 121.5)	45.7 (10.1, 81.6) 36.8 (6.7, 67.9)	34.4 (17.8, 51.3) 29.7 (6.1, 54.1)					
B2. Dynamic Effects Polynomial Model (months and months-sque	ared)							
Predicted Treatment Effects per \$100								
Estimated at Month 12	43.2 (24.0, 63.6)	44.7 (17, 73.1)	31.4 (16.6, 46.5)					
Estimated at Month 24	91.8 (69.1, 115.3)	52.4 (12.6, 93.8)	39.2 (16.9, 62.6)					
Count of Estimates								
0 to 18 months since first transfer 19 to 36 months since first transfer 37 to 54 months since first transfer	15 12 0	4 9 1	23 16 1	3 4 0	6 6 0	20 18 3		
55 to 108 months since first transfer 146 months since first transfer	0 0	0 0	1 0	0 0	0 0	0 0		

95% credibility intervals in parentheses. All currency values are reported in 2010 USD PPP. Panel A1 and B1 consider the months since first transfer for every disbursement schedule, whereas in Panels A2 and B2 we present estimates at months 12 and 24 since the first (last) transfer for ongoing stream (lump sum and ended stream) programs. The distinction between disbursement schedules in the polynomial model captures the dissipation effects of ongoing programs relative to the first transfer, whereas for ended streams and lump sum programs (i.e., ended programs) dissipation effects are presented relative to the months since the last transfer. Due to data limitations and the similarity of average results, we estimate dynamic effects jointly on ended programs in the polynomial model. Due to data limitations of the Stock of Total Assets, the parameters for months and months-squared interacted with ongoing streams (i.e., ended programs in the polynomial model. Cur dataset for Monthly Household Consumption uses treatment effects on total consumption. Treatment effects on non-durable consumption of documents of total consumption. Treatment effect per total transfer amount (Panel A) is our preferred outcome variable for ended programs. Treatment effect per monthly tranche amount (Panel B) is our preferred outcome variable for ended programs.

(0.51, 2.06) (0.58, 1.06) 95% credibility intervals in parentheses (Columns 8 and 11). Currency values reported in 2010 USD PPP. We use monthly tranche amount for ongoing streams and total transfer amount for lump sums and completed streams. Column 2 reflects the number of months elapsed since the last transfe and the measurement of the outcome. For most studies this was identical for large and small transfers, but for some they differed by a month or two; we report the median here. If the TE Ratio / Transfer Ratio in Columns 7, 8, 10 and 11 is less (greater) than 1, then there are decreasing (increasing) marginal returns with respect to transfer amount.

Table 7

95% credibility intervals in parentheses. All currency values are reported in 2010 USD PPP. A transfer is considered targeted to women (men) if the UCT is explicitely delivered to women (men) or if greater than 80% of the sample is compised of women (men). When there are at least four estimates from programs targeted to men, we conduct our analysis on all three sub-sets: Not Targeted, Targeted to Women, and Targeted to Men. When there are fewer than four estimates from programs targeted to men, we instead conduct our analysis on two sub-sets: Not Targeted to Women and Targeted to Women. We do not present results on total hours worked or stunting due to data limitations. Our dataset for **Monthly Household Consumption** uses treatment effects on total consumption when reported; we use treatment effects on non-durable consumption or food consumption when total consumption is unavailable. Our analysis controls for whether food and durable goods are included in total consumption. Our dataset for **Monthly Income** uses reported treatment effects on total household or individual income when reported; if treatment effects are only reported by sub-category of income, e.g., wage earnings, non-farm enterprise profits, etc., then the sub-category with the highest control group mean is used instead. See Appendix Table D.1. for a comparison to analysis that only uses reported estimates on total household or individual income. Effects with seven or fewer estimates have been grayed out.

24-Month Stream Program46.533.61.41.148-Month Stream Program66.543.71.51.2Costs and benefits are presented as a proportion of the transfer amount (monthly tranche for stream and total amount for lump sum). Total cost and benefit are discounted to the month of program onset using a 5% discount rate. We use our estimated treatment effects on monthly household consumption from Table 6 to calculate the total benefit. In Panel A, we use our estimates from Panel A1 and B1 of Table 5, assuming that short-term effects are constant until month 18 and long-term effects are constant after month 18. In Panel B, we use our estimates from Panels A2 and B2 of Table 5. In Panel B, we assume our dynamic effects persist as predicted by our model until benefits dissipate to zero. 24% is the median administrative costs as a proportion of the transfer of the 10 of 72 programs that report costs. 24% is also the average administrative cost for all programs with a minumum of 6% and

maximum of 93%.

6 Appendix

6.1 Study search

We develop a initial sample by collecting studies from two secondary sources: the GiveDirectly Cash Evidence Explorer and the Overseas Development Institute's 2016 report "Cash transfers: what does the evidence say?" (*Cash Evidence Explorer* 2023; Bastagli et al. 2016). We also use the publicly available data from three existing meta-analyses on cash transfers: Kondylis and Loeser 2021; Manley, Alderman, et al. 2022, and McGuire et al. 2022. From these sources, we identify 47 studies.

After building this initial sample, we conduct searches on Google Scholar, EconLit, and the AEA RCT Registry with the following search terms:

Database	Search terms	Search settings	Number of
			results
Google	(randomized, OR evaluation, OR	n/a	4,797
Scholar	experiment) AND unconditional AND		
	("cash transfer", OR "cash grant"),

6.2 Data selection and harmonization

This section outlines how we extract estimates from the papers in our sample and then convert them to as comparable units as possible before running our Bayesian meta-analysis.

Regression specification:

We apply the following set of rules to decide which treatment effects to extract from papers:

- Sometimes papers pool results across different UCT treatment arms (that vary either by disbursement schedule or transfer amount). When multiple regression specifications are reported, we prefer estimates with more disaggregation by treatment arm.
- 2. When impacts are measured across multiple rounds of data collection, we prefer estimates from regressions with more disaggregated effects by survey round.
- 3. Except for the two rules above, we prefer estimates from the simplest regression specification (i.e., the regression specification that is closest to a simple mean comparison). In practice, this means:
 - (a) We prefer estimates from regressions with fewer controls (except for treatment arm indicators, survey round indicators, and stratification indicators).
 - (b) We prefer estimates from regressions on untransformed outcome variables over log, inverse hyperbolix sine, or other transformations.
- 4. When both intent-to-treat (ITT) and treatment-on-the-treated (TOT) impacts are reported, we prefer ITT estimates.²²
- 5. We exclude treatment effects reported as odds ratios.

 $^{^{22}\}mathrm{No}$ TOT effects are included in our analysis.

Outcome selection

Consumption: We extract treatment effect estimates on total consumption. If total household consumption is not reported, we extract the reported category of consumption with the largest control group mean, typically non-durable or food consumption. Estimates on food consumption are also extracted as a primary outcome.

Food security: If a paper reports multiple outcomes on food security, we select only one outcome for inclusion in our analysis. We prioritize outcome selection in the following order: international food security scores and indexes (e.g., HFIAS, HHS, etc.), paperspecific food security indexes, hunger indicators, and finally meal frequency indicators.

Stock of total assets: When total Assets is not reported, we use either productive/business assets or consumption/household/durable assets instead. If both productive assets and consumption assets are reported, we use whichever has the bigger control group mean as the substitute for total assets. Productive assets, consumption assets, and financial assets are also extracted as secondary outcomes.

Stock of financial assets: Stock of financial savings of the household.

Monthly Income: When total income is not reported but some sub-category of total income (e.g., wage earnings, business profits, etc.) is reported, we use the sub-category with the largest control group mean as the preferred treatment effect for total income. Wage earnings, non-farm enterprise profits, agricultural enterprise profits, all household enterprise profits, and enterprise revenues are also extracted as secondary outcomes.

Hours worked per week: We extract estimates on the number of hours worked per a unit of time, typically a week.

Labor force participation: We extract treatment effects on binary variables of whether the respondent participated in any economic activity over a given period of time, typically a month. In other words, we're looking for estimates on whether participants engaged in any income-generating activity, whether self-employment or working for wage, salary, or commission. As secondary outcomes, we also extract binary variables on whether the participant engaged in any non-farm self-employment, farm self-employment, or (non-self) employment.

School enrollment: We extract treatment effects on binary variables on whether the survey respondent (or their child) is enrolled in school. If such a variable is unavailable, we instead use estimates on the proportion of children in the household enrolled in school.

Anthropometrics: We extract treatment effects on height-for-age and weight-for-age z-scores as well as stunting. Stunting is not reported enough for much of our analysis, but we do report the main results for average treatment effects (i.e., not disaggregated by distribution type or other design features).

Psychological well-being: If a paper reports multiple outcomes on psychological wellbeing, we select only one outcome for inclusion in our analysis. We prioritize outcome selection in the following order: standard psychological well-being scores or indexes (e.g., GHQ-12, WVS Life Satisfaction Scale, WHO Quality of Life Scale, etc.), standard mental health/depression scores or indexes (e.g., CES-D, PSS, GDS, etc.), paper-specific psychological well-being score or index, psychological well-being indicators, and mental health/depression indicators.

Data harmonization

Monetary units conversion: We convert all monetary units to 2010 USD PPP using the following rules:

- 1. If an amount is reported in USD PPP, we simply convert it to 2010 price levels using USD inflation.
- 2. If an amount is reported in local currency units (LCU), we convert it to USD PPP

using the contemporary World Bank PPP Conversion Factor (PPP CF) and then to 2010 price levels using USD inflation.

3. If an amount is reported in nominal USD, we convert it to LCU using the contemporary nominal USD exchange rate, then to USD PPP using the contemporary PPP CF, and finally to 2010 price levels using USD inflation.²³

Unit transformations: Recall that we prioritize extracting estimated treatment effects from regressions on untransformed outcome variables. When estimates are only reported on transformed outcome variables, we use the following calculations to account for the transformation.

- 1. Percent change: We multiplied the estimate by the counterfactual mean (typically the control group mean at endline).
- 2. Inverse hyperbolic sine: Same as percent change.
- 3. Log: For an estimate β , we multiplied $(e^{\beta} 1)$ by the control group mean.

Monthly household consumption conversions: Treatment effects on consumption vary widely in their reporting across papers. We convert all reported treatment effects to monthly household consumption using the following calculations.

- If consumption is reported over 1 week or 2 weeks, we multiply the treatment effect by 4.3 or 2.15 respectively. If consumption is reported annually, we divide the treatment effect by 12.
- 2. If consumption is reported on a per capita basis, we multiply the treatment effect by the average household size as reported in the balance table. If household size is

 $^{^{23}}$ We do not follow this approach for the two programs in our sample that take place in Liberia, because the World Bank PPP Conversion Factor applies USD, which is legal tender in Liberia. We thus convert nominal USD directly to USD PPP before adjusting for USD inflation.

not reported, we assume it is equal to 5.6 for the calculation, the mean household size in the sample.

3. If consumption is reported on a per adult equivalent basis, we multiply the treatment effect by the average number of adult equivalents per household. If this number is not reported, we use the household size as reported in the balance table to estimate the number of adult equivalents in the household. To make this calculation, we count the first member of the household as 1 adult equivalent, the second member of the household as 0.7 adult equivalents, and all subsequent household members as 0.5 adult equivalents. For example, we estimate a household of 5 to contain 3.2 adult equivalents. If household size is not reported, we assume there are 3.5 adult equivalents per household (i.e. we assume the household size is 5.6).

Food security standardization: We standardize all food security treatment effects by dividing by the control mean standard deviation if necessary. See Appendix Table B.1 for the unstandardized treatment effects.

Assets conversions: Total assets is stock, rather than flow variable, so no further conversion is necessary after converting to common monetary units. We do the same for secondary assets outcomes: productive assets, consumption assets, and financial savings.

Monthly income conversion: We convert all reported treatment effects on income to monthly income using the same methods as points 1 and 2 under Consumption Conversion. Note that unlike for consumption, we do not convert to the household level. Papers vary in their reporting of treatment effects on income at the individual or household level. Rather than trying to adjust for this discrepancy across papers, we assume researchers only measured income at the individual level if they had good reason to expect the impact of the treatment would be almost entirely at the individual, not household, level. We follow the same approach for sub-categories of income.

Hours worked per week conversion: If total hours worked is reported per month, we

divide the treatment effect by 4.3.

Labor force participation conversion: We convert proportions to percentage points by multiply by 100, if necessary.

School enrollment conversion: We extract two types of education outcomes: a binary indicator of whether a given student is enrolled in school or continuous 0-1 variable of the proportion of children enrolled in school in a given household. We treat these different measures as equivalent. When necessary we convert proportions to percentage points by multiplying by 100.

Anthropometrics conversion: We extract treatment effects on height-for-age (HAZ) and weight-for-age z-scores (WAZ), which have equivalent units by construction. No conversion is necessary. Similarly, papers that report stunting use a standard definition. We merely scale from proportions to percentage point units when necessary.

Psychological well-being standardization: We standardize all psychological well-being treatment effects by dividing by the control group mean standard deviation if necessary. See Appendix Table B.2 for the unstandardized treatment effects.

12	stream	030	20	32	Quanty of life index	standard Deviations	0.01 (0.02)	U(1)	0.01 (0.02)

Standard errors reported in parentheses. All currency values are reported in 2010 USD PPP. Specific citations associated with each Program ID reported in Table A.1. Reported outcomes have been transformed when necessary so that higher values indicate greater food security. Standardized treatment effects in Column 10 are calculated by dividing the unstandardized treatment effect in Column 8 by the control group mean standard error in Column 9. All values have been transformed if necessary so that higher values represent better psychological well-being and lower values represent worse psychological well-being.

Agricultural Enterprise Profits	17.9	6.3	7
	(-2.4, 38.9)	(-0.9, 13.8)	(5)
All Household Enterprise Profits	2.7	1.0	7
	(-15.4, 21)	(-5.4, 7.4)	(7)

Appendix Table D.1
Treatment Effects on Total Monthly Income: Alternative Income Measures

95% credibility intervals in parentheses. All currency values are reported in 2010 USD PPP. Our dataset for **Monthly Income** as reported in Table 3 uses reported treatment effects on total household or individual income when reported; if treatment effects are only reported by sub-category of income, e.g., wage earnings, non-farm enterprise profits, etc., then the sub-category with the highest control group mean is used instead. We compare this to analysis from a model that separately estimates parameters for total income (only using estimates reported on total household or individual income) and for various sub-categories of income.

Treatment Effects on Stock of Total Assets: Alternative Asset Measures								
	(1)	(1) (2)						
	Predicted Treatment Effect of \$100 Transfer	Predicted Treatment Effect of Median Transfer Amount (Panel A = PPP\$523 Panel B = PPP\$35)	Estimates (Programs)
